Abstract
Lack of a uniform definition is responsible for underrecognition of the prevalence of malnutrition and its impact on outcomes in children. A pediatric malnutrition definitions workgroup reviewed existing pediatric age group English-language literature from 1955 to 2011, for relevant references related to 5 domains of the definition of malnutrition that were a priori identified: anthropometric parameters, growth, chronicity of malnutrition, etiology and pathogenesis, and developmental/functional outcomes. Based on available evidence and an iterative process to arrive at multidisciplinary consensus in the group, these domains were included in the overall construct of a new definition. Pediatric malnutrition (undernutrition) is defined as an imbalance between nutrient requirements and intake that results in cumulative deficits of energy, protein, or micronutrients that may negatively affect growth, development, and other relevant outcomes. A summary of the literature is presented and a new classification scheme is proposed that incorporates chronicity, etiology, mechanisms of nutrient imbalance, severity of malnutrition, and its impact on outcomes. Based on its etiology, malnutrition is either illness related (secondary to 1 or more diseases/injury) or non–illness related, (caused by environmental/behavioral factors), or both. Future research must focus on the relationship between inflammation and illness-related malnutrition. We anticipate that the definition of malnutrition will continue to evolve with improved understanding of the processes that lead to and complicate the treatment of this condition. A uniform definition should permit future research to focus on the impact of pediatric malnutrition on functional outcomes and help solidify the scientific basis for evidence-based nutrition practices. (JPEN J Parenter Enteral Nutr. 2013;37:460-481)

Keywords
pediatrics; outcomes research/quality; nutrition assessment; growth; malnutrition; undernutrition

Evaluation of nutrition status and provision of adequate nutrition are crucial components in the overall management of children during illness because malnutrition is prevalent and affects normal growth, development, other clinical outcomes, and resource utilization.1 Large-scale international studies have attributed a majority of all childhood deaths to undernutrition, with high relative risks of mortality for severe malnutrition.2,3 In the developed world, malnutrition is predominantly related to disease, chronic conditions, trauma, burns, or surgery (henceforth referred to as illness-related malnutrition in this article). Illness-related malnutrition in children may be attributed to nutrient loss, increased energy expenditure, decreased nutrient intake, or altered nutrient utilization. These factors are seen frequently in relation to acute illnesses such as trauma, burns, and infections, as well as chronic diseases such as cystic fibrosis, chronic kidney disease, malignancies, congenital heart disease (CHD), gastrointestinal (GI) diseases, and neuromuscular diseases. In addition to the anthropometric changes in acute malnutrition, chronic malnutrition may be characterized by stunting (decreased height velocity).

Although several studies have reported a prevalence of illness-related malnutrition of 6%–51% in hospitalized children, this condition is probably underrecognized.4–6 Lack of uniform definitions, heterogeneous nutrition screening practices, and failure to prioritize nutrition as part of patient care are some of the factors responsible for underrecognition of the prevalence of malnutrition and its impact on clinical outcomes. To date, a uniform definition of malnutrition in children has remained elusive. Current terminologies such as protein-energy malnutrition, marasmus, and kwashiorkor describe the effects of malnutrition but do not account for the variety of etiologies and dynamic interactions that are relevant to nutrition depletion in children. A better definition of malnutrition is essential to reach the following goals: (a) early identification of those at risk of malnutrition, (b) comparison of malnutrition prevalence between studies and centers, (c) development of uniform screening tools, (d) development of thresholds for intervention, (e) collection of meaningful nutrition data, and (f) evidence-based analysis of the impact of malnutrition and its treatment on patient outcomes.7 To address this issue, an interdisciplinary American Society for
Parenteral and Enteral Nutrition (A.S.P.E.N.) working group of physicians, nurses, dietitians, and pharmacists was assigned the task of developing a uniform and comprehensive definition of malnutrition based on available evidence and multidisciplinary consensus. The working group reviewed the existing literature and developed a consensus on the important elements that should be included in a definition of pediatric malnutrition. This document describes the result of this multidisciplinary effort, including the rationale and proposal for a novel definition of pediatric malnutrition. Malnutrition includes both undernutrition and obesity. For the purpose of this document, only undernutrition will be discussed. The definition will not address malnutrition in the developing world or neonates (younger than 1 month old). Although a majority of evidence is expected to represent hospitalized children, the definition will address children in all settings.

Executive Summary

A novel and comprehensive definition of pediatric malnutrition is proposed. A multidisciplinary working group identified 5 key domains relevant to the definition of pediatric malnutrition (see Figure 1). After a systematic review of the literature along these domains, the evidence was presented and synthesized to generate recommendations for a uniform definition. The process was completed by consensus for each domain, using an iterative process. The new classification scheme incorporates the chronicity, etiology, and severity of malnutrition (see Table 1 and Table 2). This scheme also accounts for the mechanism by which nutrient imbalance results in malnutrition, association with inflammation, and its impact on growth, development, and functional outcomes. A simultaneous effort to develop specific diagnostic criteria for identifying and classifying the severity of malnutrition based on anthropometric parameters is currently under way and will be published in the future.

In summary, pediatric malnutrition (undernutrition) is defined as an imbalance between nutrient requirement and intake, resulting in cumulative deficits of energy, protein, or micronutrients that may negatively affect growth, development, and other relevant outcomes. Based on its etiology, malnutrition is either (1) illness related (1 or more diseases/injuries directly result in nutrient imbalance) or (2) caused by environmental/behavioral factors associated with decreased nutrient intake/delivery (or both). Environmental factors that result in malnutrition or negatively affect its remediation often involve socioeconomic conditions associated with inadequate food availability or complicating behavioral disorders such as anorexia and food aversion. Malnutrition is classified as either acute (fewer than 3 months in duration) or chronic (duration of 3 months or more). Chronic malnutrition may manifest with growth deficits, especially diminished height velocity (stunting), which is a hallmark of this condition that may be observed earlier than 3 months in the course of malnutrition. Hospital-acquired malnutrition refers

Table 2. Executive Summary of Recommendations.

<table>
<thead>
<tr>
<th>Domain</th>
<th>Recommendations</th>
</tr>
</thead>
</table>
| **A. Anthropometric variables** | - Record weight, height, body mass index, and mid–upper arm circumference (MUAC), and consider triceps skin fold (TSF) and mid-arm muscle circumference on admission and then serially, using appropriate growth charts. MUAC and TSF require a trained professional to obtain these measurements.  
- Head circumference must be obtained in infants younger than 2 years.  
- When feasible, a single trained individual using standardized technique and devices should perform these anthropometric measurements for nutrition assessment in individual patients.  
- Measure an infant’s length supine on a length board until age 2 years, after which time they should be measured upright. For children older than 2 years and unable to stand, consider using an alternative measurement (eg, tibia length, knee height, arm span) for a height proxy.  
- Weigh infants and children with minimal clothing on scales accurate to at least 100 g.  
- Use existing technology (beds with accurate scales) to weigh children who are bedridden.  
- Use the 2006 World Health Organization charts as a population standard against which individual growth and nutrition characteristics should be described for children up to 2 years of age who are measured in the supine position for length.  
- For children aged 2–20 years, use the Centers for Disease Control and Prevention 2000 charts with a standing height measurement used for plotting. Healthcare centers may use their electronic health records systems to develop an efficient system of documenting and plotting serial measurements against the reference or standard curves.  
- Use the z score to express individual anthropometric variables in relation to the population reference standard.  
- When assessing nutrition status on admission or first hospital visit, anthropometric parameters should be recorded and plotted on reference/standard age-appropriate curves to obtain the z score.  
- Classify severity of existing/current nutrition state based on cutoffs for individual anthropometric parameters. Specifics of parameters and their cutoffs will be discussed in a separate document. |
| **B. Growth** | - Use dynamic changes in weight and length velocity over time as compared with a single measured parameter.  
- Use a decline in z score for individual anthropometric measurement (eg, a decrease of more than 1) as the indication of faltering growth. This threshold must prompt investigation into the etiology of growth failure and potential interventions.  
- Details of recommended frequency of measurements and cutoffs for severity will be described in a separate document from the Academy of Nutrition and Dietetics. |
| **C. Chronicity of malnutrition** | - Use 3 months as a cutoff to classify duration of malnutrition as acute (<3 months) or chronic (3 months and longer). |
| **D. Etiology of malnutrition and etiology and pathogenesis** | - When malnutrition is secondary to a disease/injury, use the term *illness-related malnutrition* in the definition and include the specific disease or condition (acute or chronic) if it is directly responsible for nutrient imbalance.  
- Include a description of the predominant mechanism leading to nutrient imbalance in the definition. Review and include the most common mechanisms for pediatric malnutrition: (a) decreased intake/starvation (eg, fluid restriction, cardiac failure, anorexia nervosa), (b) increased requirement/hypermetabolism (eg, burn injury), (c) excessive losses (chronic diarrhea, burns, proteinuria), and (d) failure to assimilate (absorb or use) the delivered nutrients (eg, malabsorption states).  
- Include more than one mechanism if mechanisms exist simultaneously.  
- Recognize the role of inflammation on nutrition status.  
- Consider including the presence of inflammation in the definition when laboratory parameters such as C-reactive protein and cytokines are conclusive.  
- Hospital-acquired malnutrition in children is malnutrition that is acquired or worsened after admission to the hospital. Perform nutrition screening at admission to detect children at higher risk of nutrition deterioration during the illness course.  
- Awareness of nutrition deterioration during hospitalization will highlight the impact of disease on nutrition state and provide opportunities for improvement in hospital system of care. This should be documented as “worsening malnutrition” as soon as it is evident during the illness course. |
| **E. Impact of malnutrition on functional status** | - Consider developmental assessment and neurocognitive monitoring in determining the impact of chronic malnutrition in children.  
- Include lean body mass measurement (by body composition measurement or anthropometric techniques) with some measure of muscle strength as a meaningful and quantifiable expression of outcomes affected by malnutrition in children.  
- Use validated objective measures of body composition and uniform assessment techniques for muscle strength in children. |
to nutrient imbalance acquired during hospitalization and may occur with or without preexisting malnutrition, or malnutrition that was present prior to hospital admission.

The mechanisms of nutrient imbalance in illness-related malnutrition include decreased nutrient intake, altered utilization, increased nutrient losses, or increased nutrient requirements (hypermetabolism) not matched by intake. These basic mechanisms may be interrelated, and more than one mechanism is often involved. In addition, there is much more to be learned about disease-specific disruptions of normal metabolic pathways in acute and chronic illness. It is anticipated that the definition of malnutrition will continue to evolve with improved understanding of the diverse processes that lead to and complicate the treatment of this condition. It is widely believed, for example, that the presence and severity of inflammation influence illness-related malnutrition and should be included in its definition. However, the precise role of inflammatory processes in the evolution and treatment of pediatric malnutrition awaits further research in disease-specific pathophysiology as well as the development of specific and cost-effective measuring tools. Children with malnutrition are expected to fall into 1 of the 2 main categories described in Table 3.

Finally, a meaningful definition of malnutrition must include a quantifiable continuum of outcomes affected by specific nutrient imbalances. In addition to anthropometric parameters (height, weight, head circumference [HC]), suggested outcomes affected by malnutrition include achievement of age-appropriate developmental milestones, lean body mass measurements, muscle strength, immune function or dysfunction, frequency or severity of acquired infections, wound healing, length of hospitalization, and disease-specific resource utilization. Reaching consensus on a definition of pediatric malnutrition should permit future research to focus on the impact of malnutrition on pediatric functional outcomes and will help solidify the scientific basis for evidence-based nutrition practices.

**Background**

The World Health Organization (WHO) defines malnutrition as “the cellular imbalance between the supply of nutrients and energy and the body’s demand for them to ensure growth, maintenance, and specific functions.”

This dynamic imbalance of nutrients affects children differently than adults and can have profound implications for the developing child. A uniform definition of pediatric malnutrition is desirable. At the outset, the working group identified key concepts or domains that would be incorporated in the pediatric malnutrition definition. These 5 domains—anthropometric parameters, growth, chronicity of malnutrition, etiology and pathogenesis, and developmental/functional outcomes—were included in the overall construct of the definition. The distinction between acute and chronic malnutrition may have important bearing on the interventional strategy used in its management. Hence, the chronicity of the nutrient imbalance must be accounted for in a definition. Screening for malnutrition on admission to a healthcare facility or at the beginning of an illness allows

*aSeverity of malnutrition is determined by anthropometric measurements and the relationship of these parameters with standard/reference charts. The specifics of anthropometric variables and thresholds for classifying the degree of malnutrition will be discussed in a separate document.

*bThe presence or absence of inflammation influences disease-related malnutrition and must be indicated in the definition when improved markers of inflammation become available in the future.
assessments of current nutrition status and facilitates early detection of subsequent nutrition deterioration related to the illness. Disease type and severity is an important variable that dictates nutrient needs and the ability to deliver and assimilate nutrients. Furthermore, there is increasing recognition of the prevalence of disease-related malnutrition that includes an inflammatory component. The complex interplay between inflammation and nutrition is not well characterized in children, but contemporary definitions of malnutrition will need to account for the impact of inflammation on nutrition status. Finally, no definition of malnutrition is complete without addressing its impact on functional outcomes. The myriad effects of macronutrient and micronutrient deficiencies on outcomes such as growth, body composition, muscle strength, intellectual and developmental ability, and overall quality of life are perhaps most important in the pediatric age group.

### Method

The Pediatric Malnutrition Definitions Workgroup was formed in April 2010, and members were assigned the task of reviewing existing pediatric age group English-language literature published between 1955 and 2011. Identified studies were also searched for relevant references related to the 5 domains of the definition that were determined a priori. Each domain was subdivided into concepts and questions (see Table 4). Keywords used for searches generally included pediatrics, nutrition, malnutrition, and undernutrition and then, specifically for each of the domains, the following:

A. Anthropometric variables: weight, weight loss, height, HC, body mass index (BMI), body composition, nutrition screening and assessment, nutrition history, anthropometrics, survey, muscle mass, fat-free mass, lean body mass, and intake

B. Growth: growth charts, WHO, Centers for Disease Control and Prevention (CDC), wasting, and stunting

C. Chronicity of malnutrition: chronic vs acute malnutrition, hospital length of stay, growth charts and curves, height stunting over time, weight loss over time, and lean body mass loss over time

D. Etiology and etiopathogenesis: disease state, socioeconomic status, poor intake, malabsorption, pathophysiology of pediatric malnutrition, energy balance, inflammation, congenital defects, acute inflammatory (injury, infection, etc), chronic inflammatory disease, child nutrition disorders/etiology, malabsorption, and abnormal nutrient distribution

E. Impact of malnutrition on functional status: developmental delays, muscle function, cognitive abilities, growth and development, behavior, cognition, strength, social ability, muscle strength, hand strength, pinch strength, performance, hand grip strength (HGS), maximal HGS, dominant hand maximal HGS, peak power, force plate, loss, accrual, muscle motor function, motor skills, cognition, cognitive development, schooling, grade, IQ score, intelligence, IQ, cognitive, Binet or Raven or Peabody, and neuropsychological function

The best available literature starting with primary references was obtained and carefully reviewed. Any prospective randomized controlled trials (RCTs), controlled cohort studies, or systematic reviews were analyzed. Evidence tables were formatted to display the evidence for each domain to guide the definition.

</table>
| A. Anthropometric variables | 1. What anthropometric variables should be measured when assessing nutrition status in hospitalized children?  
2. Which reference data (National Center for Health Statistics vs World Health Organization growth curves) should be used to plot the individual measurements?  
3. Which statistical method should be used to classify nutrition status as deviation from population central tendency? (SD, percentile, or z score) |
| B. Growth | 1. What are the objective parameters for detecting abnormal growth (eg, crossing percentiles, change in z-score for anthropometric variable)? |
| C. Chronicity of malnutrition | 1. How is malnutrition classified based on duration: acute vs chronic? |
| D. Etiology of malnutrition and etiology and pathogenesis | 1. What is the impact of underlying illness/injury on nutrition status?  
2. What are the potential mechanisms leading to nutrient imbalance?  
3. What is the relationship between inflammation and nutrition status?  
4. Was malnutrition present at admission? If so, has there been deterioration of nutrition status during this hospital stay? |
| E. Impact of malnutrition on functional status | 1. What are the adverse outcomes affected by pediatric malnutrition? |
Recommendations were provided on the scope of each of these domains based on available evidence and by an iterative process to arrive at a multidisciplinary consensus.

**Results**

The following sections summarize the results of the literature reviews and summary recommendations to the questions developed in the 5 domains.

**Domain A: Anthropometric Variables for Assessing Nutrition Status**

**Question A1. What anthropometric variables should be measured when assessing nutrition status in hospitalized children?**

Assessment of malnutrition involves accurate measurements of anthropometric variables such as weight and length/height, which are plotted on population growth curves against which an individual child is compared. However, there remains considerable controversy regarding the most useful measurement and inconsistency in the anthropometric parameters used, or the statistical measures employed to characterize the individual nutrition state. Table 5 summarizes some of the classification schemes for pediatric malnutrition.

In 1956, Gomez et al introduced a classification of malnutrition based on weight below a specified percentage of median weight-for-age. To distinguish stunting (chronic malnutrition) from wasting (acute malnutrition), the calculation of height-for-age was introduced. In 1977, Waterlow et al recommended the use of percentiles and standard deviations (SDs) below the median to define underweight, wasting, and stunting. These definitions with subsequent WHO modifications continue to be used widely. Table 6 includes studies that have described the use of anthropometric parameters for defining and classifying pediatric malnutrition.

However, accurate serial weight and height measurements are challenging to obtain in hospitalized children. Obtaining serial weights and heights is generally a low priority. Also, a large proportion of patients do not have these measurements recorded during their course in the hospital. Furthermore, acute illness is often associated with fluid retention and edema that make weight measurements unreliable. In addition to daily fluid shifts, the accuracy of measurements would be affected by dressings, tubing, and other equipment required for care. Critically ill children are often deemed too ill to be moved for weight measurements. The use of in-bed scales may allow accurate serial weighing in this population, especially in infants and neonates. As a result, alternative anthropometric tools have been proposed for assessing malnutrition. Mid–upper arm circumference (MUAC) has been suggested as a proxy for weight and HC as a proxy for height. In the patients with fluid shifts and edema, MUAC may be a better indicator than weight-for-height for classification of acute malnutrition. MUAC changes little during the early years. It is simple and accurate, and it predicts malnutrition-related mortality with reasonable specificity and sensitivity. Prospective studies in Asia have reported that MUACs of <110 mm predict the risk of death from malnutrition within 6 months. Mid-arm muscle circumference (MAMC) may be calculated from MUAC and triceps

BMI, body mass index; CBC, complete blood count; FTT, failure to thrive; GI, gastrointestinal; HIV, human immunodeficiency virus; IBW, ideal body weight; ICU, intensive care unit; LOS, length of stay; MUAC, mid-upper arm circumference; RSV, respiratory syncytial virus; SGA, small for gestation age; TSF, triceps skin fold; W/H, weight-for-height.
skin fold (TSF) using the formula MAMC = MUAC – (TSF × 0.314). TSF alone may be a useful screening variable in children. However, its accuracy in children with extensive muscle wasting may be questionable. The standard of care is to measure recumbent length (also known as supine) for infants and children younger than 2 years and standing height for those older than 2 years. However, it is often difficult (if not impossible) to obtain a standing height with acutely ill children, as well as nonambulatory populations (eg, cerebral palsy). In such cases, there are various methods available for obtaining linear measurements, each with strengths and shortcomings. Many portable length boards can convert into stadiometers and thus could feasibly be used to measure recumbent length for older children (eg, measuring table). Notably, if recumbent length and standing height (ie, stature) are obtained on the same person, there is a difference of approximately 0.8 cm (1/3 inch), with standing height measuring less than recumbent length. Obtaining a recumbent length measurement without proper equipment (ie, measuring tape on a bed) does not yield accurate results. If a measuring table is not available, it is recommended to obtain an alternative proxy measure of height, such as arm span, knee height, or tibia length. An in-depth discussion of each technique is beyond the scope of this article, but additional information can be found in the literature.

BMI is calculated as weight in kilograms divided by height in meters squared, and it can be used to express weight adjusted for height. To account for variability by sex and age, BMI in children is compared with sex- and age-specific reference values. BMI cutoffs have been suggested as criteria for defining thinness in children and adolescents. The 17-kg/m² thinness cutoff in this study is close to the −2 SD cutoff for wasting. In adolescents with eating disorders, the percentage of expected body weight (EBW) is used clinically for diagnosis of anorexia nervosa and as a threshold for management decisions. A patient with <75% EBW is likely to meet the criteria for severe malnutrition and admission to an inpatient facility. However, there are concerns regarding the existing methods used to derive this threshold, as they use different reference data. The use of weight-for-height and BMI does not yield equivalent EBW determinations and may affect clinical decisions. HC is a useful index of nutrition status and brain development and is associated with scholastic achievement and intellectual ability in school-aged children. The long-term effects of severe undernutrition at an early age may result in delayed HC growth, delay of brain development, and decreased intelligence and scholastic achievement, variables that are strongly interrelated. In their study of 96 right-handed healthy high school graduates (mean ± SD age 18.0 ± 0.9 years) born at term, Ivanovic et al examined the interrelationships between head size and intelligence, learning, nutrition status, brain development, and parental head size. In this study, HC and brain volume were negatively correlated with undernutrition during the first year of life.

The validity of individual anthropometric parameters may vary based on the population of children. Hence, a combination of measurements obtained by a trained individual in combination with other clinical parameters should guide nutrition assessment in children. Serial anthropometric measurements are absolutely necessary to assess optimal growth during the course of illness.

Recommendation A1
- Record weight, height, BMI, and MUAC and consider TSF and MAMC on admission and then serially using appropriate growth charts. HC must be obtained in infants younger than 2 years.
- When feasible, a single trained individual (usually a dietician) using standardized techniques and devices should perform these anthropometric measurements for nutrition assessment in individual patients.
- Measure infants’ length supine on a length board until 2 years of age, after which time they should be measured upright. For children older than 2 years and unable to stand, consider using an alternative measurement (eg, tibia length, knee height, arm span) for a height proxy.
- Weigh infants and children with minimal clothing on scales accurate to at least 100 g.
- Use existing technology (such as beds with accurate scales or Hoyer lifts) to weigh children who are bedridden.

These are recommendations for anthropometric parameters that should be incorporated in the definition. Future studies will help further evaluate the importance of each of these variables, including the role of body composition measurements, in defining malnutrition and the response to nutrition interventions.

Question A2. Which reference data (CDC vs WHO growth curves) should be used to plot the individual measurements? The WHO adopted the National Center for Health Statistics (NCHS) classification in 1983 as the international reference to classify children as underweight, wasted, or stunted. The CDC’s 2000 percentile curves were developed in an effort to address some of the concerns regarding extrapolation of NCHS data to heterogeneous populations. The charts include a set of curves from birth to 36 months of age and a set for children and adolescents 2–20 years of age. The 2000 CDC growth charts more closely matched the national distribution of birth weights than did the NCHS growth charts and could be used to obtain both percentiles and z scores. In 2006, the WHO adopted a new population standard based on an international multicenter study using exclusively breastfed children of diverse ethnic backgrounds from 6 diverse geographical regions: Brazil, Ghana, India, Norway, Oman, and the United States. The WHO Multicentre Growth Reference Study (MGRS) was conducted between 1997 and 2003. The study combined longitudinal follow-up of 882 infants from birth to 24 months with a cross-sectional component of 6669 children aged 18–71 months. The study populations lived in...
socioeconomic conditions favorable to growth, and mothers followed healthy practices such as breastfeeding and not smoking during and after pregnancy. Hence, the new WHO standards depict normal human growth under optimal environmental conditions and can be used to assess children everywhere, regardless of ethnicity, socioeconomic status, or type of feeding. These standards demonstrate that healthy children from around the world who are raised in healthy environments and follow recommended feeding practices have strikingly similar patterns of growth. Weight-for-age, length/height-for-age, weight-for-length/height, and BMI-for-age percentile and \( z \) score values were generated for boys and girls aged 0–60 months. The WHO charts reflect growth patterns among children who were predominantly breastfed for at least 4 months and were still breastfeeding at 12 months of age. The use of the new WHO growth standards is recommended for infants aged 0–24 months.

For children between the ages of 2 and 5 years, both the new WHO and the CDC 2000 charts are available. The data-gathering techniques for both charts were similar for this age group. To avoid multiple transitions between charts for plotting growth parameters during a child’s lifetime, the use of CDC charts for all children 2 years and older is appropriate.\(^{38}\) The methods used to create the WHO and CDC charts are similar after 24 months of age, and the CDC charts can be used continuously through 19 years of age. Hence, transitioning at age 24 months is feasible because measurements switch from recumbent length to standing height at this age, necessitating the use of new printed charts. Table 7 summarizes studies that have reported the use of growth charts for

definitions of pediatric malnutrition. Some studies have shown that the WHO growth reference curves result in a higher measured prevalence of malnutrition when compared with NCHS standards. There is some variability in practice related to correcting for gestational age in premature infants. Most premature infants are expected to catch up with their peers by age 2–3 years. The American Academy of Pediatrics (AAP) policy clarifies the use of “corrected (adjusted) age” for premature infants until 3 years of chronological (postnatal) age. This value is calculated by subtracting the number of weeks of gestation at birth from 40 weeks of gestational age.

**Recommendation A2**
- Use the 2006 WHO charts as a population standard against which individual growth and nutrition characteristics should be described for children up to 2 years of age who are measured in the supine position for length.
- For children and adolescents (aged 2–20 years), use the CDC 2000 charts with a standing height measurement used for plotting. Healthcare centers may use their electronic health records (EHR) systems to develop an efficient system of documenting and plotting serial measurements against the reference or standard curves.
- Use corrected age (number of weeks/months premature + chronological age) for preterm infants until they are 3 years old.

These recommendations mirror those by the CDC and the AAP. Future studies examining the use of growth charts incorporated in EHRs that allow easy plotting of anthropometric parameters and visual displays of growth are desirable. EHRs may also include prompts for missing anthropometry in hospitalized patients.

**Question A3.** Which statistical method should be used to classify nutrition status as deviation from population central tendency? A variety of statistical scales are used worldwide to describe anthropometric parameters and diagnose malnutrition in children (Table 8). Percentage of median refers to the ratio of a child’s weight to the median weight of a child of the same height in the reference data, expressed as a percentage (eg, if the median weight of the reference data for a particular height is 10 kg, then a child weighing 8 kg is 80% weight-for-height). Percentiles rank the position of an individual’s measurement on the reference curves, indicating what percentage of the population will be less or greater than that individual (eg, if 10% of the reference population weighs less than the child being considered, then the child is on the 10th percentile). The z-scores describe how far (in standard deviation or SD units) a child’s weight is from the mean weight of a child at the same height in the reference data. For example, an observation value that has a z-score of −1 is 1 SD less than the mean on a normal/Gaussian curve of the reference data set. Hence, 34% of the values in the data set are expected to have a z-score between zero (mean) and −1. z-scores have been used for several years now, and the WHO has recommended the use of z-scores in expressing anthropometric measures, especially when describing groups of subjects. z-Scores allow more precision in describing anthropometric status than does the customary placement “near” or “below” a certain percentile curve. For example, the phrase “below the third percentile” does not distinguish between a child who is just below this point (whose z-score may be −2.1) from one with severe growth faltering (whose z-score may be −3.5 or lower). Similarly, 3% of normal children will weigh less than the third percentile, but a z-score significantly lower than −2.0 clearly indicates a growth problem. CDC computer programs allow calculations for anthropometric data such as weight-for-height and weight-for-age, which can be expressed as z-scores without needing extensive manual plotting and calculations. Recent EMRs allow plotting of anthropometric parameters on exact percentiles, and some also provide calculations of z-scores for values recorded.

Refer to the appendix for additional resources on determining z-scores for anthropometrics. When using percentiles or z-scores, “average” is the median (50th percentile) when percentiles are used, but “average” is the mean when z-scores are used.

**Recommendation A3**
- Use the z-score to express individual anthropometric variables in relation to the population reference standard.
- When assessing nutrition status on admission or first hospital visit, anthropometric parameters

should be recorded and plotted on reference/standard age-appropriate curves to obtain the \( z \) score. Serial measurements are absolutely necessary for longer hospital stays.

- Classify the severity of existing/current nutrition state based on cutoffs for individual anthropometric parameters. Specifics of relevant parameters and frequency of measurements and their cutoffs will be discussed in a separate document.

**Domain B: Growth**

**Question B1.** What are the objective parameters for detecting abnormal growth? Failure to thrive (FTT) is a term used to describe children who are not growing as expected. It is estimated that up to 5 in 100 infants and children in the United States have FTT. Although other factors may be responsible for FTT, more than 90% of cases in most studies do not have an underlying medical cause, and virtually all causes are identified by a careful history and physical exam. Environmental and behavioral causes predominate, and detrimental effects of chronic malnutrition on neurocognitive development are well documented. Recommendations for treating and evaluating children with mild growth deviations in primary care settings and a standardized definition of FTT that warrants more intensive treatment would help ensure that children are referred appropriately and that resources are focused on the highest risk children.

It is generally agreed that growth faltering or FTT should be defined by deterioration in anthropometrical parameters, but there is no consensus regarding the specific anthropometrical criteria. Failure to gain weight is generally used, with a cutoff of around the fifth percentile for weight-for-age. In addition to the above method of using cutoff values for attained growth, it is necessary to assess the progression of growth chronologically when evaluating malnutrition or FTT. When defining FTT based on growth velocity, the most commonly used criterion is “downward crossing of more than two major percentile lines” or “being among the slowest gaining 5% on a conditional weight gaining chart (which compares an infant’s current weight with that predicted from their previous weight)”.

A decrease in weight-for-age \( z \) score has been used to define growth failure and as an outcome measure in several recent studies. A decrease in weight-for-age of more than 0.67 \( z \) score during the first months after surgery for congenital heart defects, corresponding to a downward percentile crossing through at least one of the displayed percentile lines on standard growth charts, is strongly related to late mortality in children undergoing cardiac surgery. In contrast, long-term surviving children showed a mean increase in weight-for-age \( z \) scores after the final operation. Hence, there is increasing use of \( z \) scores and changes in \( z \) scores for anthropometric measurements. There seems to be a trend toward using \( z \) scores as a uniform strategy to define and classify malnutrition and growth failure for the purposes of scientific investigation and community interventional programs.

Although recommendations for the frequency of obtaining serial anthropometric measurements are available, these need to be further reviewed before uniform application. A potential problem in the hospital setting could be the lack of access to historical data to determine growth patterns. EHRs may help to bridge this gap in information across different settings. Until such measures are in place, the ability of the hospital-based clinicians to evaluate trends in anthropometric parameters may be limited in some patients.

**Recommendation B1**

- Use dynamic changes in weight and length velocity over time as compared with a single measured parameter.
- Use a decline in \( z \) score for individual anthropometric measurement (eg, a decrease of more than 1) as the indication of faltering growth.
- The threshold for anthropometric deterioration must prompt investigation into the etiology of growth failure and potential interventions.

**Domain C: Chronicity of Malnutrition—Acute vs Chronic**

**Question C1.** How is malnutrition classified based on duration: acute or chronic? Acute malnutrition results in weight decline that is hallmark by a decrease in the patient’s weight-for-height. Chronic malnutrition is most often identified by a faltering height-for-age and affects long-term growth as a result of chronic nutrition deficiency. The distinction between acute and chronic illness is based on time. The NCHS (www.cdc.gov/nchs/ich.htm) defines chronic as a disease or condition that lasts 3 months or longer. Chronic malnutrition may be characterized by stunting (decreased height velocity). This is a characteristic of chronic malnutrition that may be irreversible and manifest earlier than 3 months if nutrient deficiency is severe.

**Recommendation C1**

- Use 3 months as a cutoff for delineation between acute (<3 months) or chronic (≥3 months) malnutrition.
- Chronic malnutrition may be characterized by height-for-age (HFA) that is less than −2 \( z \) scores.

**Domain D: Etiology and Pathogenesis of Malnutrition**

**Question D1.** What is the impact of underlying illness on nutrition status? The prevalence of malnutrition varies depending on the underlying medical conditions, ranging from 40% in patients with neurologic diseases to 34.5% in those with infectious disease, 33.3% in those with cystic fibrosis, 28.6% in those with cardiovascular disease, 27.3% in oncology patients, and 23.6% in those with GI diseases. Patients with multiple
diagnoses are most likely to be malnourished (43.8%). In a population of children scheduled for elective surgery in a tertiary referral hospital, 51% of children were malnourished. In their study of 424 children aged 30 days or older, Joosten et al documented a prevalence of 11% acute malnutrition and 9% chronic malnutrition upon admission to the hospital. The strongest predictor of malnutrition upon admission was the presence of underlying disease. Children with acute malnutrition had a longer hospital length of stay than those without. In this study, malnutrition was determined by the presence of any one of the following cutoffs: (a) weight-for-height (WFH) SD score lower than −2, (b) WFH less than 80% of the median, (c) % ideal body WFH less than 80%, (d) WFH less than fifth percentile, or (e) BMI SD score of less than −2. A uniform definition of malnutrition is expected to provide a more accurate prevalence of malnutrition in children and hence allow determination of the impact of specific disease states on nutrition status. Table 9 summarizes studies demonstrating the impact of specific diseases on nutrition status in children.

Children with CHD have a high incidence of protein-energy malnutrition (PEM), which contributes to the poor outcome in this cohort. Common reasons for energy deficits in children with CHD include decreased intake, increased energy expenditure (attributable to cardiac failure or increased work of breathing), and malabsorption (attributable to increased right-sided heart pressure, lower cardiac output, or altered gastrointestinal function). Longer hospital length of stay and frequency of readmission were significantly correlated with poor nutrition status in children with single-ventricle physiology, and aggressive enteral nutrition (EN) and parenteral nutrition (PN) were associated with better nutrition status. Patients in this study demonstrated continued nutrition deterioration over time, and a majority were severely underweight at the time of subsequent hospitalization for major cardiac surgery. Studies with aggressive nutrition interventions and home monitoring programs are currently under way by facilities through the National Pediatric Cardiology Quality Improvement Collaborative.

Children with burn injuries manifest a prolonged hypermetabolic stress response, with a catabolic state that can persist for weeks after the initial injury. Poor intake in this group results in energy deficits, and the negative effects of energy deficit on nutrition status may persist for months after injury. Decrease in lean body mass has been shown for up to a year after the burn injury, with delayed linear growth reported for up to 2 years after burn injury. One in every 5 children admitted to the pediatric intensive care unit (PICU) experiences acute or chronic malnutrition. The increased energy demands secondary to the metabolic stress response to critical illness, failure to prescribe adequate nutrients, and delay or failure to administer the prescribed nutrients are factors responsible for the subsequent deterioration of nutrition status in children admitted to the PICU. Therefore, acute and chronic malnutrition have been shown to worsen at discharge from the PICU. Several other groups of patients are deemed at a higher risk of malnutrition, including children with cystic fibrosis, oncologic illnesses, GI diseases, and neurologic impairment. Eating disorders represent the third most common chronic disease in adolescents after obesity and asthma. Recently, hospitalizations for children younger than 12 years with eating disorders have increased significantly. Eating disorders may indeed be biologically based and probably constitute a major cause of undernutrition in the pediatric age group in industrialized nations.

Hence, the definition of malnutrition must include specific conditions that contribute to the nutrition state. The mechanisms responsible for nutrient deficits in these patients may vary.

**Recommendation D1**

- Include the specific disease condition in the malnutrition definition if it is directly responsible for energy and/or protein imbalance.

For example, a patient with a burn injury resulting in acute deterioration of nutrition status should be classified as having burn-related acute malnutrition.

**Question D2. What are the potential mechanisms leading to the nutrient imbalance?** Malnutrition is the result of an imbalance between nutrient requirement and intake/delivery. A variety of mechanisms may alter this balance in hospitalized children. Malnutrition typically occurs along a continuum of inadequate intake and/or increased requirements, impaired absorption, and altered nutrient utilization. Weight loss or impaired growth can occur at multiple points along this continuum. Individuals may also present with inflammatory, hypermetabolic, and/or hypercatabolic conditions. Table 10 summarizes studies in which some of these mechanisms are elucidated.

**Recommendation D2**

- Include a description of the most predominant mechanism leading to nutrient imbalance in the definition. Review and include the most common mechanisms for pediatric malnutrition: (a) decreased intake/starvation (eg, fluid restriction, cardiac failure), (b) increased requirement/hypermetabolism (eg, burn injury), (c) excessive losses (chronic diarrhea, protein-losing enteropathy, burns, proteinuria), and (d) failure to assimilate (absorb or use) the delivered nutrients (eg, malabsorption states, cystic fibrosis, short bowel syndrome).

- Include more than one mechanism if mechanisms exist simultaneously.

**Question D3. What is the relationship between inflammation and nutrition status?** Inflammatory conditions may increase requirements for nutrients while promoting a nutrient-wasting catabolic state. Illness-related malnutrition is associated with an inflammatory component. Inflammation promotes

skeletal muscle breakdown, mediated by a cytokine-driven pathway. Critical illness or injury promotes an acute inflammatory response that has a rapid catabolic effect on lean body mass. The acute phase inflammatory response is associated with elevated resting energy expenditure and nitrogen excretion and thereby energy and protein requirements, respectively. Nutrition supplementation alone only partly reverses or prevents muscle protein loss in active inflammatory states. The anorexia that accompanies inflammation will promote further loss of lean tissue if nutrition intake is inadequate. Over the past decade, it has become increasingly evident that the pathophysiology of disease or injury-associated malnutrition invariably includes acute or chronic inflammation that affects body composition and functional ability. The inflammatory condition may be short-lived or chronic in nature with the severity being influenced by the progression and extent of underlying illness/disease condition. Loss of muscle mass and function may occur insidiously in the chronic disease state over months to years. It is important to recognize the presence or absence of a systemic inflammatory response in the malnourished state, as it affects the response to intervention. In the absence of inflammation, as seen in malnutrition due to starvation, appropriate nutrient interventions may be successful in treating malnutrition. On the other hand, the presence of inflammation may limit the effectiveness of nutrition interventions, and the associated malnutrition may compromise the clinical response to medical therapy. If inflammation is present, then it is useful to clarify whether it is mild, moderate, or severe and transient or sustained. The recently proposed adult malnutrition definition has suggested that acute disease-related malnutrition is probably associated with a severe degree of inflammation and chronic disease-related malnutrition with a mild to moderate degree of inflammation. However, the role of inflammation and currently available inflammatory markers, such as C-reactive protein (CRP) or erythrocyte sedimentation rate, in classifying pediatric malnutrition severity has not been adequately described.

Inflammatory cytokines can impair growth via multiple pathways. Anorexia, skeletal muscle catabolism, and cachexia affect the growth plate via insulin-like growth factor 1 (IGF-1)–independent or IGF-1–dependent pathways. The inhibitory effects of tumor necrosis factor–α (TNF-α) and interleukin (IL)–1β on the growth plate are reversed by anti–IL-1β and anti–TNF-α. The effect of TNF-α on IL-6 transcription and circulating leptin level may be reversed by infliximab. In pediatric Crohn’s disease, growth retardation may result from a complex interaction between nutrition status, inflammation, disease severity, and genotype, which causes resistance to the effects of growth hormone. Elevated serum concentration of CRP is one of the most common nontraditional markers used to stratify cardiovascular risk, and it has been used to identify patients with chronic inflammation as it reflects a proinflammatory state. IL-6 concentrations may be an important marker of early inflammatory response with serial levels correlating with nutrition status in critically ill children. Although there is no doubt about the association between inflammatory state and nutrition recovery, the precise nature of this relationship remains elusive. Furthermore, despite evidence of a key role for the inflammatory cytokines such as TNF-α, IL-6, and IL-1β, these are not routinely measured outside the research setting. The list of clinical inflammatory markers currently used in practice is at best rudimentary, and their relevance in malnourished states needs to be examined. Research efforts aimed at examining the validity of newer biomarkers of the inflammatory state are urgently needed.

**Recommendation D3**
- Recognize the role of inflammation on nutrition status.
- Include the presence of inflammation with available laboratory parameters such as CRP and cytokines in the definition.

Future studies examining biomarkers of inflammation and the impact of the inflammatory state on malnutrition in children are highly desirable.

**Question D4. Is there a distinction between malnutrition at admission vs malnutrition acquired during the hospital stay?** The nutrition status of children often declines after admission to the hospital, resulting in early and serious consequences, such as slowing of growth and increased susceptibility to various infections. This has mainly been attributed to the poor awareness and the lack of education of healthcare providers and adverse hospital routines. Children with severe acute illness or severe trauma often experience extreme metabolic stress. Although “on admission,” these patients often present without a prior history of malnutrition, the presence of the massive inflammatory response seen in the acute phase of injury or critical illness limits the effectiveness of nutrition interventions and can contribute to the rapid development of malnutrition. Periods of interrupted feeding, imposed to accommodate the variety of medical-surgical interventions needed to stabilize these patients, also contribute to the development of malnutrition despite the clinician’s best efforts to provide adequate energy and other nutrients. Although malnutrition acquired after admission to the hospital is frequently associated with a risk of adverse clinical events and a longer hospital stay leading to higher healthcare costs, it is a problem that remains largely underestimated and often unrecognized. In a single-center study at a tertiary hospital in Brazil, more than half of the children lost weight after admission during their hospital stay, and around 10% of well-nourished children became malnourished. In an Italian center, children with an admission BMI-for-age z score lower than −2 SD showed a mean BMI decrease at the end of their hospital stay, which was significantly higher than in
children with better nutrition status at admission. In this study, the investigators defined nutrition deterioration as a drop in the BMI z score by 0.25 or more during the hospital stay. One in every 5 children had a significant decrease in BMI z scores that was already detectable by the third day after admission. This suggests the possibility of early detection of children who are at risk for worsening malnutrition and the ability to establish an appropriate nutrition management strategy to prevent the development of such adverse conditions during their hospital stay.

There is increasing interest in determining the impact of hospitalization (disease, intervention, nutrition, and other factors during the hospital course) on nutrition status. Hence, a distinction between nutrition state on admission and change in nutrition state or acquisition or worsening of malnutrition during the hospital course is relevant. Admission assessment will allow identification of malnourished patients and provide opportunities to prioritize nutrition interventions in this group. Serial nutrition assessments during the hospital stay will help identify those with subsequently worsening nutrition status. Heightened awareness, multidisciplinary approach, and prioritization of sound nutrition practices may help decrease some of the preventable causes of acquired or worsening malnutrition.

**Recommendation D4**
- Perform nutrition screening at admission to detect children at higher risk of nutrition deterioration during the illness course. Awareness of nutrition deterioration during illness will highlight the impact of disease on nutrition state and provide opportunities for improvement in care at a system level.

**Domain E: Functional Status**

**Question E1. What are the functional outcomes affected by pediatric malnutrition?** A well-known consequence of malnutrition is muscle dysfunction, as reflected by decreased grip strength. HGS correlates with the loss of total body protein and has been shown to be a good marker of immediate postoperative complications and predictive of major complications in adult cirrhotic outpatients. Decreased HGS is also a predictor of loss of functional status in hospitalized patients. Recent observations in healthy children aged 6–18 years have extended our knowledge of normal variation of this characteristic with age, sex, size, and body composition and could be used as a reference pattern. HGS increases with age, and a significant sexual dimorphism from age 12 years is observed. HGS detects a high prevalence of nutrition risk in patients with cirrhosis and Crohn’s disease in remission. However, the use of HGS in pediatric populations is limited and may not be feasible in infants and younger children. Pediatric studies that evaluate the use of HGS or similar measures of muscle function in nutrition assessment are urgently required.

Lack of adequate macronutrients or selected micronutrients, especially zinc, selenium, iron, and the antioxidant vitamins, can lead to clinically significant immune deficiency and infections in children. Undernutrition in critical periods of gestation and neonatal maturation and during breast milk weaning impairs the development and differentiation of a normal immune system. Infections are both more frequent and more often become chronic in the malnourished child. Micronutrients act as antioxidants and as cofactors at the level of cytokine regulation. Because the immune system is immature at birth, malnutrition in childhood might have long-term effects on health. Optimal nutrition provides nutrients and factors that have been shown to modulate immune maturation and response to inflammation. In addition, enteral nutrients alter gut microflora and may affect antigen exposure. The mechanisms by which early nutrition affects immune responses in childhood need further elucidation.

No aspect of our physical or psychological existence is not affected in some way by nutrition. A profound lack of nutrition would obviously have a negative influence on all aspects of development, and such effects of malnutrition are well documented. In a cohort study of 20 children who had been fed a thiamine-deficient infant formula, investigators assessed language, mental development, and motor development. In comparison to matched controls without nutrition deficiency, the children with thiamine deficiency had receptive and expressive language delay, as well as delayed age at independent walking. In individual studies, young children who had FTT followed for up to 8 years had measurable IQ deficits as well as learning and behavioral difficulties. A meta-analysis in 2004 suggested that FTT in infants may result in long-term problems in cognitive development with a 4.2 IQ point decrement. Malnourished children also have increased rates of infection and behavioral problems, including impaired communication skills and attention-deficit hyperactivity disorder.

Environmental factors such as malnutrition during critical periods may modify the risk for the development of many common diseases later in life. This phenomenon is probably explained by epigenetics, the interindividual variation in DNA patterns. There are scarce data on the critical interrelation between early nutrition, growth, development, and subsequent health and the influence of early nutrition on epigenetic modifications. The role of optimal nutrition in preventing the development of diseases later in life needs further exploration. Malnutrition may also affect other outcomes such as wound healing, length of hospital stay, and resource utilizations. Adverse outcomes must be included in the definition of pediatric malnutrition, and future research examining the impact of malnutrition on relevant clinical outcomes is urgently needed.

**Recommendation E1**
- Consider developmental assessment and neurocognitive monitoring in determining the impact of chronic undernutrition in children.
- Include lean body mass measurement with some measure of muscle strength as a potentially
identifiable outcome adversely affected by malnutrition in children.
- Use validated objective measurements of body composition and uniform assessment techniques for muscle strength in children.

Future studies aimed at describing the nexus between nutrition state and immunity during illness are urgently required. Biomarkers of immune dysfunction may be incorporated in the definition of nutrition as an outcome in the future.

**Pediatric Malnutrition Classification**

In summary, pediatric malnutrition (undernutrition) is defined as an imbalance between nutrient requirement and intake, resulting in cumulative deficits of energy, protein, or micronutrients that may negatively affect growth, development, and other relevant outcomes. On the basis of discussions for each domain outlined above, we propose a new framework for defining pediatric malnutrition (see Figure 1). This schema for defining malnutrition incorporates the concepts of chronicity, etiology, and pathogenesis of malnutrition; its relationship with inflammation; and its impact on functional outcomes. Malnutrition for an individual child should be diagnosed based on the anthropometric parameters and their cutoffs. In addition to the anthropometric definition, the new definition of malnutrition will include a diagnostic relationship between what is known about the causative disruption of normal nutrient pathways by the patient’s illness or home environment and the presumptive effect (ie, the patient-specific expression of this nutrient imbalance as a negative outcome). This requires the inclusion of specific disease states if such disease(s) has already contributed to or is expected to result in nutrition vulnerability and deterioration. Hence, malnutrition will be characterized as illness related (secondary to disease, condition, surgery, or injury) and/or not illness related (secondary to environmental factors). Occasionally, pediatric malnutrition may be characterized as both illness related and environmental (ie, one may be primary but exacerbated by the other). Furthermore, the specific pathway leading to malnutrition is incorporated in the definition and may include one or more of the following: (a) decreased nutrient intake (starvation), (b) increased requirement of nutrients, (c) increased nutrient losses, and (d) altered nutrient utilization. Finally, one or more anthropomorphic or developmental outcomes is included if deleterious and felt to be a manifestation or cause/effect of the malnourished state. The role of inflammation is acknowledged by indicating its presence along with illness-related malnutrition. Acquired malnutrition is defined as further deterioration of nutrition status of children in relation to their nutrition state on admission.
